2 SRAL Internal Calibration Monitoring.

2.1 Introduction

The SRAL instrumental calibration is assessed during the mission. Several parameters are monitored and analysed in detail in order to characterise the altimeter performance along the mission lifetime.

Two main groups of calibration parameters are monitored.

The first is derived from the Point Target Response (PTR) calibration in CAL1 mode. The PTR signal follows the same circuitry path as the science waveforms within the calibration loop. The delay caused by the travel through the calibration path can be measured and afterwards compensated in the total range computation. The attenuation suffered by the signal when traveling through the instrument also needs to be monitored and the science waveforms need to be compensated for this power variations. Moreover, there are a collection of other parameters to be checked, such as the PTR width and the secondary lobes features. These CAL1 parameters are produced separately for LRM and SAR modes, as they follow different instrumental paths, and also they are duplicated for Ku-band and C-band. Moreover there are different options for characterising the delay and power of the closed loop signal, such as the PTR maximum power or PTR maximum position.

The second is related to the Instrument Transfer Function, measured by the CAL2 mode. The science waveforms spectra is distorted by the on-board instrumental hardware sections. Therefore, in order to retrieve the original echo shape, we need to compensate for this effect. Several parameters are derived from the analysis of the CAL2 waveforms for characterizing it and dissect any feature along the mission lifetime. The CAL2 waveform is the same for both modes LRM and SAR, but there is a distinction between bands Ku and C.

Additionally, for SAR mode, the two intra-burst corrections are monitored: they are the power and phase progressions within a burst. Science pulses within a burst are to be corrected for these expected variations in the burst. Some characteristics are computed for describing and following up their behaviour along the S3 mission.

It is also of major importance the monitoring of the on-board clocks. The altimeter clock counter, responsible for computing the echo travel time, has a multiplicative impact in the range determination. The platform clock is responsible for the overall platform instruments datation. Their stability and performance are to be supervised along the mission.

Finally, the data coming from the thermistors located in the different sections of the on-board HW (HKTM products), are to be analysed in order to check the relation of any calibration parameters anomaly with the thermal behaviour, and find solutions for modelling the instrument characterisation (for instance orbital oscillations) if needed.

An important remark is to be made: although we can see a certain drift of a specific calibration parameter along the mission, this is not to be considered as a warning for the quality of the science data, as long as the instrumental calibration is correctly applied during the science data processing. A warning shall be raised in the scenario of a calibration parameter value approaching the mission requirement bounds. The

Autocal parameters monitor the actual attenuation values for each on-board ATT step, and are to be used for updating the on-board ATT table in case of need.

2.2 Cyclic In-Flight Internal Calibration.

In this chapter, the monitoring of all calibration modes main parameters for the S3A and S3B missions is depicted in figures (only Ku band). An analysis of the cycle results is developed in chapter 2.3.

2.2.5 Housekeeping Temperatures

The CAL1 SAR mode is assumed representative of the general SRAL thermal behaviour.

2.3 Cyclic SRAL Status Summary

This section is dedicated to a summary of the cyclic performances and status of the altimeter parameters exposed in section 2.2. It covers both S3A and S3B missions.

For the analysed cycle, none of the calibration parameters is showing a significant anomalous behaviour. Nonetheless, some specific observations are explained here below.

The absolute values of the S3A parameters are similar to the S3B ones.

In general, the LRM and SAR performances are similar for a given band (Ku or C).

The main CAL1 parameters cyclic statistics are detailed in Table 2-1 and Table 2-2, respectively for S3A and S3B missions.

The S3A CAL1 power trend for Ku band is no longer close to -1 dB/yr as at the first cycles of the mission. It presents a decreasing trend but less negative than at BOM.

The Ku band CAL1 time delay slopes are higher than previous cycle, although having maximum absolute values below 1.5 mm/year.

The Ku band CAL1 width drifts are several orders of magnitude below the nominal PTR width value.

CAL2 parameters are stable and nominal. They are similar between the two missions.

AutoCal tables are nominal for both missions, and present very different attenuation steps arrays. This is not due to a fundamental difference between the S3A and S3B instruments design, but due to a different strategy for reaching the same theoretical attenuation steps values.

The thermistors values are showing generally a stable series over the analysed period.

All these observations are related to the different SRAL calibration parameters during this cycle. A whole mission monitoring is developed in section 2.4. Some of the cycle behaviours could give us the idea of a significant change of rate, but when observed within the full mission scenario, they come into scale.

Table 2-2. Collection of S3B calibration parameters statistics for all modes and bands covering the cycle period.

2.4 Mission SRAL Status Summary

The main SAR Ku L1b calibration parameters series of S3A and S3B missions are gathered and plotted in this section, in order to observe their whole missions behaviour.

The plotted calibration parameters are:

- CAL1 time delay
- CAL1 power
- PTR width
- Burst corrections (power and phase) and their slopes
- CAL2 waveform ripples shape, plus the waveforms slopes and de-trended standard deviations
- Autocal averaged differences and attenuation progression

The SAR mode thermistors series are also plotted after reading the CAL ISP TM products.

Additionally it is represented a simulation (power model fitting) of the S3A CAL1 SAR Ku Integrated Power for 20 years of mission, in order to foresee how long the SRAL Power would meet the mission requirements based in the current behaviour. This need comes from the warning raised at BOM due to high CAL1 Power trends.

The "whole mission" figures and tables avoid a period at BOM. For the S3A mission, the considered series starts at 27/5/2016 (Cycle 4, orbit 302). For the S3B mission it starts at 12/7/2018 (Cycle 10, orbit 210). The BOM period include calibration parameters behaviours that, if included in our monitoring results, can disturb the analysis and projections made for the rest of the mission. At BOM the main parameters tend to show opposite trends with respect to the routine phase, and in the case of S3B, several operational mode changes cause jumps in the series.

Page: 36

We can see from the above figures and its legends a general agreement between the S3A and S3B calibration parameters absolute values.

The most important and notable drift observed in the whole missions series is the S3A CAL1 SAR Ku Power series, presenting a significant power decay at BOM (about -1 dB/year). Anyhow, we can see a slow stabilisation of this parameter along the mission, being below -0.5 dB/year from cycle 31.

A mission requirement of the CAL1 SAR Ku power is a maximum power drop of 3.5dB from beginning of mission. Below that power bound, the sea-ice and ice sheets geophysical measurements could be impacted, due to a poor SNR. A power model fitting has been computed for the S3A mission, and the assumption is to reach the limit by 2034.

For S3B, there are some spikes of CAL1 SAR Ku power of around 0.05 dB. These values coincides with products presenting a different calibration sequence, which could influence the operational point of the SRAL instrumentation, mainly SSPA/HPA. In addition, there are specific noisier periods during 2018, which are related to the existence of different operating tracking modes (acquisition or tracking) before the calibration sequence activation, which impacts the initial conditions of the instrumental path performance. The rest of the periods are less noisy due to working in Open Loop tracking mode, where no acquisition mode is needed.

The S3A PTR time delay has also decreased its negative trend, being currently almost flat. The S3B time delay trend shows periods of diverse drifts along the mission, but at a long term, it is positive.

The Ku band PTR widths of both missions have trends that are several orders of magnitude below their absolute values, and similar to their standard deviation. The S3A mission presents a clearer negative long-term trend, while S3B changes locally its behaviour.

The intra-burst corrections along the missions are quite stable. The S3A burst power slope shows a clear annual behaviour (oscillations of less than 0.2 mdB/pulse) due to sensibility to instrumental thermal changes. The annual behaviour is more difficult to be detected in the S3B figure yet, due to a shorter period of observation and an added slope, but we detect also a correlation with thermal conditions on-board (see April and September 2019 events). The burst phase slope is increasing along the missions, around 1.5 mdeg/pulse per year for S3A and around 6 mdeg/pulse per year for S3B.

From the attenuation steps progression in dB we can check, for each ATT step, the delta in attenuation with respect to the first record value. The tendencies are visible for specific attenuations in each mission, with excursions (see colour code at right hand side) of less than 0.1 dB.

The CAL2 parameters behaviour is stable and nominal along the missions. The flagging of certain CAL2 parameters is dismissed in order to properly plot the series: it is needed a mission L1b reprocessing for homogenizing the flagging along the mission, for instance in the CAL2 slope.

The thermistors data series are showing annual oscillations, and a long-term cooling. At some dates there are increases of the S3A thermistors values of around 0.2°C, returning in a short term to its precedent values, with a very limited impact in the calibration series.

There is a peak in the S3B temperatures on board at date 2018/11/22 (e.g., THR1 is 3°C up). This event affects slightly the calibration parameters (for instance the CAL1 SAR Ku Time Delay presents a jump up of 1mm).

In S3B, from cycle 21 - orbit 239 (2019/01/29) to cycle 22 - orbit 96 (2019/02/15), the thermistors values were not written in the TMs, and are consequently not represented in the figures. This anomaly was caused after a restart due to a SMUG event. A new command for a restart was executed and fixed the anomaly successfully.

The collection of statistics for the main calibration parameters for both modes and bands of S3A and S3B missions is depicted below in Table 2-3 and Table 2-4 respectively.

The long term drift for the S3A time delay and power variables is higher in absolute terms for the Ku band than for the C band, the Ku band ageing is faster than the one from C band, probably caused by the more stressed Ku band instrumental operations (e.g. bursts transmission & reception only in Ku band). All standard deviations are computed without detrending.

As a general observation, we can say that the behaviour of all calibration parameters is nominal.

2.5 On-board Clock Performance

The altimeter USO clock frequency has a major multiplicative impact in the determination of the altimeter range. The USO clock is the one that drives the chirp generation and controls the acquisition time (window delay or tracker range) of the returned echo signal. Here below are depicted the USO frequency impact on the altimeter range for S3A (Figure 2-60) and S3B (Figure 2-61).

The USO clock frequency impact in the range has a constant trend around 4.5 mm per year for the S3A mission and around 2 mm per year for the S3B mission.

The USO impact in the range can change around an orbit considering an elliptical orbit and the variations on the surface elevations, but these differences are far below the nominal absolute values.

In addition, the temperatures on-board can make the clock suffer frequency fluctuations, but as we can see in the previous figures, there are no visible effects of this kind so far.

2.6 SRAL Dedicated Investigations

This chapter is devoted to the investigations derived from observations along the mission. The on-going investigations results will be updated in each new version of the report; solved issues will be dismissed from the report.

isardSAT has processed the TRP data from a list of L1A products. Passes with IPF-SR-1 Version 06.13 (cycle 3 to 23) use reprocessed L1A and L2 data provided on the ftp.s3rep.acri-cwa.fr FTP server. Passes from cycle 24 to 45 increase in IPF-SR-1 Version as newer ones become available, up to Version 06.14 for the most recent passes.

The range bias results are of the order of millimetres. The datation bias is of the order of hundreds of microseconds.

For S3A, the passes on cycles 13, 21 and 54 have not been analysed because the transponder was not switched on due to extreme climate conditions and passes on cycle 48 and 50 have not been analysed due to maintenance work. For S3B, cycles 1 to 7 and 15 to 18 have not been included as the satellite was not overflying the TRP. The TRP was not switched on due to extreme snow event for cycle 20.

Figure 2-62 to Figure 2-65 depicts the series of TRP processing results for the two missions and the two transponders, including range, datation, stack alignment and stack range noise.

Table 2-5 present the results from the Crete TRP passes processing. The range bias is computed as measured minus theoretical. The results for S3A show a positive measured range, 7.36 mm larger than expected (elevation 7.36 mm shorter than expected), and a datation bias of -125.71 microseconds, both extracted from the minimisation of the RMS between theoretical and measured series. They also show a 0.81 mm stack noise. For S3B, the results show a negative measured range, 6.61 mm smaller than expected (elevation 6.61 mm higher than expected), and a datation bias of -24.80 microseconds, both extracted from the minimisation of the RMS between theoretical and measured series. They also show a 0.83 mm stack noise. It is interesting to note that for S3B the results from cycle 21 show that the datation bias has been reduced from -114.60 microseconds (passes were in tandem orbit following S3A) to residual values.

The regression line in Figure 2-62 shows a drift of 0.43 mm/year, but it has a very low significance.

Table 2-6 presents the results from the TRP passes over Svalbard. The results for S3B show a negative bias range, 68.56 mm smaller range than expected (elevation 68.56 mm higher than expected), and a datation bias of -46.31 microseconds, both extracted from the minimisation of the RMS between theoretical and measured series. They also show a 6.73 mm stack noise (we have less than 1 mm with S3A/B over Crete and 7.4 mm with CryoSat-2 over Svalbard). For S3A, the results show a negative measured range, 102.33 mm smaller than expected (elevation 102.33 mm higher than expected), and a datation bias of -82.81 microseconds, both extracted from the minimisation of the RMS between theoretical and measured series. They also show a 14.74 mm stack noise.

Table 2-6. Results of Svalbard TRP passes processing

Regarding the geophysical corrections, for the Crete measurements the ionospheric and wet/dry tropospheric corrections were extracted from the transponder auxiliary files provided by the MPC team.

Then, the solid earth, geocentric tide and ocean loading corrections are selected from the L2 products. A table with the Geophysical corrections used is shown in Table 2-7. The TRP internal delay is 4.954 meters.
